(August 7, 2013)

Abstract: *In this work we investigate the effect of gamma and ultraviolet radiations on the thermoluminescence of Brazilian calcite. The irradiated samples presented three TL peaks at 150, 245 and 320° C (at a linear heating rate of 1.8° C/s), with a main emission band centered at 615nm due to the $^4G \rightarrow ^6S$ transition of the Mn^{2+} . The irradiated samples presented, besides the Mn^{2+} signals, three lines related to carbonate groups. The thermal treatment and the irradiation effects on the ESR signal lead to the conclusion that $(CO_3)^{3-}$, stabilized in two different symmetries, and the $(CO_2)^-$ ions are the electron trapping centers. It was found that the TL peaks follows a t^{-1} decay as a function of the UV illumination time. An alternative model for the TL emission of calcite is discussed, considering that the recombination of charges is processed via a thermally assisted tunnelling mechanism.*

I. INTRODUCTION

Calcite is a mineral found in many geological formations. Its thermoluminescence (TL) has been studied, mainly due to its application in geological and fossil dating [1–3]. Calcite can also be used for ionizing and ultraviolet radiation dosimetry.

Investigations on calcite have shown different TL characteristics depending on the impurity content and on the genesis of the sample. It was also observed on artificially grown $CaCO_3$ crystals that the type and concentration of impurities modify both TL sensitivity and glow curve shape.

Important contributions have been made to the understanding of the TL mechanism of calcite since the pioneering works of Kolbe and Smakula [4] and Medlin [5] in the sixties. Studying the influence of manganese concentration, and by comparison of the emission spectrum of calcite with the emission of the others lattices including manganese, Medlin found that the emission band centered in 615nm, corresponding to a transition from the first excited to the fundamental state of Mn^{2+} ion occupying a Ca^{2+} site. Recent works [6,7] showed

that the shape of the emission spectrum changes from a broad band without structure to a well-resolved narrow band when the temperature of the TL peak increases and when the concentration of the Mn decrease. They also concluded that the orange emission is related to Mn impurity. Calderon et al [8] suggested that the holes are trapped by the impurities and electrons are trapped at dislocations forming $(CO_3)^{3-}$. The irradiation with UV light was found to modify the intensity of the TL peaks suggesting that the trapped carriers can be phototransferred from deep to shallow traps [9]. Concerning the kinetics of the detrapping process, it was found that the isothermal decay follow a t^{-1} law which could not be accounted for a single trap model. Many workers explained this results assuming that the process are due to a distribution in the activation energies [13–15]. On the other hand, Visocekas et al [10] suggested that, for the peaks observed on their samples below room temperature, this behavior could be due to a tunnelling process.

In the present work we investigate the effect of gamma and ultraviolet radiations on the thermoluminescence of Brazilian calcite from Miranda, MS. Based on a correlation between TL and electron spin resonance (ESR) and on the photoinduced TL decay, we suggest an explanation for the appearance of the three peaks between room temperature and 450°C, and propose an alternative model for the thermoluminescence process.

II. EXPERIMENTAL

Brazilian calcite from Miranda, MS used in this work was powdered and sieved and the grains with diameters between $74\mu m$ and $174\mu m$ were selected. Chemical analysis by atomic absorption and X-ray fluorescent spectroscopy techniques detected the following impurities: Si(<0.1%), Al(<0.1%), Fe(<0.05%), Ti(<0.05%), Mg(<0.23%), Na(<0.03%) and K(<0.05%). Electron spin resonance measurements revealed the presence of manganese. Samples were exposed to ^{60}Co gamma rays from 50Gy to 500Gy. Ultraviolet irradiation was performed at a distance of 0.5 m from a high pressure 400W mercury lamp. A home made TL reader was used to heat

4 mg powder samples from 30°C to 400°C in a nitrogen atmosphere, at a heating rate between 1°C/s to 3°C/s. We performed a series of monochromatic TL measurements with wavelength varying from 450 to 750nm in steps of 10nm. Data were stored in a microcomputer and the 3D isometric plots were constructed via software after correcting each of monochromatic curves to the wavelength response of the system.

ESR experiments were performed with a BRUKER ER 200D equipment, also on powdered samples at room temperature, in the X-band and 1.0 mW microwave power (below saturation). The peak to peak height of the first derivative of the signal was considered to be proportional to the number of paramagnetic centres.

III. RESULTS

The glow curve of untreated sample (without any treatment in laboratory) consists of two peaks at 245 and 320°C when heated at a rate of 1.8°C/s. After a laboratory dose of gamma rays, the intensity of these peaks increases and another peak, around 150°C, appears. Hence for simplicity these peaks are labeled as peaks A, B, and C as their temperatures increase.

Figure 1 shows the isometric plot and the contour plot of the TL spectra of the irradiated samples. The three main peaks present a broad emission band centered at 615 nm. Besides this band, peaks A and B present a very weak emission band at 480nm, not usually reported. Comparing the TL spectra around 615nm at the peak temperatures we can see that peak C displays a fine-structure with at least 4 emission lines in this region while peak A are mainly composed by the main emission at 615nm. These results agree with previous results [6,7]. Treated samples (with a heat treatment at 400°C for 1 hour followed by a gamma irradiation) show a similar glow curve, without changes in the peak positions.

The growth and the saturation of the peak heights with the exposure to gamma rays are shown in figure 2. The effect of post-irradiated thermal treatment at different temperatures shows that the decrease of TL intensity is accompanied by the dislocation of the TL peak maxima to higher temperatures indicating that the TL processes can not be accounted for a first order kinetic. Figure 3 shows the effect of 10 min post-irradiation annealing at different temperatures. We can see that as the temperature of post-irradiation thermal treatment increases, the intensity of the TL peaks decrease. Peak A vanish first followed by peak B and finally by peak C.

The effect of ultraviolet (UV) irradiation on the thermoluminescent properties was studied using both untreated (without any treatment in the laboratory) and treated samples (with a heat treatment at 400°C for 1 hour followed by gamma irradiation). When treated samples are irradiated with UV all the three peaks decrease and the peak maxima shift to higher temperatures (Fig-

ure 4), a similar shifts is produced by thermal bleaching. To check if any isothermal reduction of the peak was happening during the UV illumination, the temperature of the samples was monitored. We found that during the UV illumination the temperature is around 30°C. Measurements of the isothermal decay of the TL peaks revealed that, considering the time intervals used in these experiments, the isothermal decay at this temperature can be neglected. Figure 5 shows the variation of the inverse of TL intensity as a function of the illumination time "t" where we can see that TL intensity of the three peaks are proportional to t^{-1} .

In figure 6 we show the result of the intensities of the ESR signals as a function of the radiation dose. The ESR measurements were performed at room temperature and it is possible to see that increasing the gamma ray doses, the well known signals of the Mn^{2+} ion present in the samples decrease. At the same time three other signals labelled 2, 3 and 5, with $g_2=2.0036$, $g_3=2.0032$, and $g_5=2.0006$ typical of free radicals, increase. The effect of the post-irradiation thermal treatment at different temperatures during 10 minutes on the labeled ESR signals are shown in figure 7. The increase of temperature of post irradiation heat treatments causes the increase of the Mn^{2+} signal and decrease firstly of the signal 3, at the 75-150°C range, followed by the signal 2, at 200-350°C, and finally the signal 5, starting at 280°C (Figure 7). Thermal treatment at 400°C during 1 hour eliminate all the 2, 3 and 5 signals produced by the irradiation.

IV. DISCUSSION

At present, the plain understanding of thermoluminescent emission requires the identification of the luminescence and the trapping centers and the indication of the charge carrier transference and recombination processes. The results presented on this work allow us to confirm the explanation presented by other researches and point out an alternative model to the charge carrier transference.

From figure 1 we can see that the three peaks have the same emission band centered on 615nm. This result combined with the result that the ESR signal related to Mn^{2+} decrease with the irradiation dose and is recovered if the sample is heated, (see figures 6 and 7), clearly establish that the Mn is the hole trap formed upon irradiating the crystal and that during the heating it is both the recombination and the luminescence center. These results agree with the results found by other authors [6,7] that pointed out that the emission band centered in 615nm is due to the $^4G \rightarrow ^6S$ transition of the Mn^{2+} ion.

ESR signals 3 ($g_3 = 2.0036$), 2 ($g_2 = 2.0032$) have been associated [11] to the $(CO_3)^{3-}$ while signal 5 ($g_5 = 2.0006$) is associated with $(CO_2)^-$. In our experiments signals 3 and 2 bleach at different temperature ranges suggesting two different types of $(CO_3)^{3-}$ on the crystal lattice. The decay of the free radical ESR signals with

increasing heat treatment temperature points out to an unambiguous correlation between the A, B and C TL peaks and 3, 2 and 5 ESR signals. From this result, combined with the growth of these signal as a function of the radiation dose described in figure 6, we can conclude that the $(\text{CO}_3)^{3-}$ and the $(\text{CO}_2)^-$ are the electron trapping centers.

The results presented by Medlin [13,14] showed that the isothermal decay of the phosphorescence of calcite crystals follows a t^{-1} law. Medlin [13] and Pagonis et al [15] attributed this behavior to a recombination processes with a distribution in the energies of the electron traps.

The $T_m \times T_{stop}$ method, initially proposed by McKeever [3] as a tool for distinguishing among different kinetics and mechanisms, was performed in natural calcite by Lima et al [16]. Their results clearly indicated that the distribution in activation energies can not account for the TL peaks in calcite.

In the present work UV light was used to release the trapped electrons and generates the electron-hole recombination process (figures 4 and 5). The results obtained from these measurements show that the decay of the gamma-ray induced TL peaks due to exposure to UV light is inversely proportional to the illumination time, as we can see from figure 5.

The detrapping rate, in this experiment, is proportional to the intensity of the UV light but the mechanism of the charge recombination and the light emission should be the same if we employed thermal activation. In the former, a distribution of traps can not explain the t^{-1} law also observed.

Taking into account all these results we are proposing that the charge transfer mechanism is processed via a thermally assisted tunnelling from the carbonate groups, as described earlier, and the Mn^{3+} . This process can explain the decay of the TL peak intensity with the UV illumination time, found in the present work, the isothermal decay of the phosphorescence in calcite, found by Medlin and Pagonis et al., and the $T_m \times T_{stop}$ results, found by Lima et al. This proposal is also in agreement with the observation that the TL peaks in calcite are not accompanied by any thermally stimulated conductivity peaks, as it was showed by Medlin [17], and that the emission of light during the recombination process is generated in a "localized-type" mechanism [18].

If the recombination of charges between the electron and the hole traps are via a tunnelling process, both centers should be close enough to enable the tunnelling process to take place. Hence, we suggest that during the irradiation of the samples the $(\text{CO}_3)^{3-}$ and $(\text{CO}_2)^-$ centers are formed in the vicinity of a Mn^{2+} substituting for a Ca^{2+} of the calcite matrix. The two different $(\text{CO}_3)^{3-}$ observed in the ESR measurements can be attributed to carbonate groups at nearest-neighbor and at next-nearest-neighbor positions of the Mn dopant.

V. CONCLUSION

In conclusion, the results observed in the present work clearly establish the role of the $(\text{CO}_3)^{3-}$ and $(\text{CO}_2)^-$ ions as the main trapping centres and the role of the Mn^{2+} as the recombination and the luminescence centre in the TL processes in calcite. The observed TL peaks can be explained as follows: during irradiation, Mn^{2+} ions change to Mn^{3+} , losing one electron that is captured in a $(\text{CO}_3)^{2-}$, forming the $(\text{CO}_3)^{3-}$ ion or the $(\text{CO}_2)^-$ ion. The $(\text{CO}_3)^{3-}$ can be formed either in a nn or in a nnn position to the Mn^{3+} dopant generating two different $(\text{CO}_3)^{3-}$ ions. Upon heating, the electron recombines with the hole left in the Mn^{3+} , after a thermally assisted tunnelling from a trap close to the manganese. The resulting Mn^{2+} is formed in an excited state, whose decay is responsible for the emitted light during the TL process.
