Abstract

It has been estimated that the entire Earth generates heat corresponding to about 40 TW (equivalent to 10,000 nuclear power plants) which is considered to originate mainly from the radioactive decay of elements like U, Th and K deposited in the crust and mantle of the Earth. Radioactivity of these elements produce not only heat but also antineutrinos (called geo-antineutrinos) which can be observed by terrestrial detectors. We investigate the possibility of discriminating among Earth compositions models, predicting different total radiogenic heat generation, by observing such geo-neutrinos, at Kamioka and Gran Sasso assuming KamLAND and Borexino (type) detectors, respectively at these places. By simulating the future geo-antineutrino data as well as reactor neutrino background contributions, we try to establish to which extent we can discriminate among Earth composition models for given exposures (in units of kt· yr) at these two sites on our planet. We use also information on neutrino mixing parameters coming from solar neutrino data as well as KamLAND reactor neutrino data in order to estimate the number of geo-antineutrino induced events.

I. INTRODUCTION

There is much about the Earth's heat engine that is unknown. The main datum is the surface heat flow, as most of the Earth is hidden from view. The total heat flux is presently estimated to be about 40 TW, which, however, suffers from uncertainties due to the size of its local variations and inaccessibility of much of Earth's surface.

We know that there are radioactive isotopes in the Earth that can produce heat through decay. Although the rate of heat generation by decay of unstable radioactive nuclides is tiny, if it is integrated over the entire volume of the Earth, total heat flux become huge. Radiogenic heat, evidently, must be an important source of internal heat production. However, questions as how much of the Earth's heat generation is from radiogenic origin, or how much from the fact that the Earth is still hot, have not yet been answered in a satisfactory way.

Antineutrinos accompany β decays of the chief radioactive isotopes ^{40}K, ^{238}U, ^{232}Th and ^{87}Rb, encountered on surface layers and supposed to exist also in interior layers. The heat that drives mechanical motion in the mantle presumably comes mostly from radioactivity. Measuring the antineutrino flux from the Earth can provide a unique way to access information on the internal structure and dynamics of our planet [1 7]. This can be done, at least for anti-electron-neutrinos coming from ^{238}U and ^{232}Th decays, the former producing 6 and the latter 4 $\bar{\nu}_e$ per decay chain within the energy reach of current and near future neutrino detectors. Neutrinos from these elements have higher energies than that come from ^{40}K and ^{87}Rb, and detectable at liquid scintillator detectors such as KamLAND [8] and/or Borexino [9] through the inverse β-decay reaction, $p + \bar{\nu}_e \rightarrow n + e^+$.

Different Earth composition models predict different total amount of U and Th in the mantle, which lead to different total heat flux from radiogenic origin. Moreover, the fact that concentration of such elements is much larger (a factor of ~ 20 times) in the continental crust (with typical thickness ~ 35 km) than the oceanic one (with typical thickness ~ 7 km) and continents and ocean are not uniformly distributed over the Earth make the geo-antineutrino flux different from place to place.

Quite recently, in Ref. [5], geo-antineutrino flux from various Earth composition models have been estimated (before the first KamLAND results are reported) and then in Ref. [6], first KamLAND data, which contained possible candidates of $\simeq 9$ geo-antineutrino events,

have been analyzed, and it was concluded that practically all Earth composition models are consistent with the current data. In this work, we will try to go beyond these works, by investigating to which extent liquid scintillator detectors such as KamLAND and/or Borexino (type) detectors can be used to help in discriminating among different geophysical models of heat production by measuring antineutrinos in the energy range $1.7 < E_{\bar{\nu}_e}/\mathrm{MeV} < 3.4$ produced inside the Earth. In deed KamLAND experiment has reported 9 (4 and 5 events associated to ^{238}U and ^{232}Th, respectively) possible candidate of geo-antineutrino events [8]. However, it is too early to conclude that they are really coming from the Earth and we need to wait for future data. We show how much one can improve the quantitative understanding of the radiogenic contribution to terrestrial heat in about a decade of operation.

Organization of this paper is as follows. In Sec. II, we describe different models of Earth's radio active elements compositions and in Sec. III, we describe our analysis method. In Sec. IV, we describe our results and finally, Sec. V is devoted to discussion and conclusion.

II. EARTH AS A ANTINEUTRINO SOURCE

Antineutrinos are produced inside the Earth in radioactive β decays mainly of ^{40}K, ^{238}U, ^{232}Th and ^{87} Rb. These elements are classified as lithophile elements in geophysics and considered to be accumulated in the Earth's crust. The abundance of these isotopes, although of prime geophysical importance, is only known at or near the surface of the Earth. Among these geo-antineutrinos, the one come from ^{238}U and ^{232}Th have higher energies. The maximal neutrino energy from the former and the latter are, respectively, $E_{\bar{\nu}_e}^{\max} = 3.26$ MeV and $E_{\bar{\nu}_e}^{\max} = 2.25$ MeV, which are above the threshold of existing anti-neutrino detector such as KamLAND.

Although the concentrations of these radioactive elements are considered to be much smaller in the mantle than in the crust, the total geo-antineutrino flux from the whole mantle can be comparable to that coming from the crust because of the much larger volume.

Here we consider, as our references, four different models which predict the distributions of ^{238}U and ^{232}Th in the Earth. We do not consider neutrinos coming from K and Rb because energies of these neutrinos are below the threshold of detectors we consider in this work. In all models uniform distribution is assumed within the crust and mantle and radioactive

activity of such elements in the core is neglected.

Since the uranium mass in the crust is estimated to be $M_c(\mathrm{U}) = 0.4 \times 10^{17}$ kg, and Si represents about 15% of the Earth mass, $M_\oplus = 5.97 \cdot 10^{24}$ kg, the other masses in the crust and in the mantle can be obtained for each model from the mass ratios they provide. Average concentration of U in the continental crust is estimated to be 1.7 ppm [15] whereas that in the oceanic one is estimated to be 0.1 ppm

The models can be thus classified by the amount of U they predict for the mantle $M_m(\mathrm{U})$. In this work, we follow the classification of models considered in Ref. [5], whose characteristic will be described below.

A. Chondritic Earth Model

The Chondritic Earth model assumes for the Earth's gross composition that of the oldest meteorites, the carbonaceous chondrites. The mass ratios for these meteorites [10] are: $M(\mathrm{Th})/M(\mathrm{U}) = 3.8$, $M(\mathrm{K})/M(\mathrm{U}) = 7\times10^4$ and $M(\mathrm{U})/M(\mathrm{Si}) = 7.3\times10^{-8}$ [11]. Radiogenic production in the chondritic model easily accounts for 75% of the observed heat flow, about 30 TW, and it could easily saturate it when uncertainties are included. U and Th provide comparable contributions, each a factor of two below that of K. In this model, by taking into account that the total mass of the mantle is 4.1×10^{24} kg (68.1 % of the total Earth mass), concentration of U in the mantle is about 0.006 ppm.

B. Bulk Silicate Earth (BSE) Model

The Bulk Silicate Earth (BSE) model provides a description of geological evidence coherent with geochemical information. It describes the primordial mantle, prior to crust separation. The mass ratios here are: $M(\mathrm{Th})/M(\mathrm{U}) = 3.8$, $M(\mathrm{K})/M(\mathrm{U}) = 10^4$ and $M(\mathrm{U})/M(\mathrm{Si}) = 9.4 \times 10^{-8}$. In this BSE model the present radiogenic production, mainly from U and Th, accounts for about one half of the total heat flow, 20 TW. The antineutrino luminosities from U and Th are rescaled by a factor 1.3 whereas K, although reduced by a factor of 5, is still the principal antineutrino source. Concentration of U in the mantle is 0.01 ppm.

C. Fully Radiogenic (FR I) Model

One can conceive a model where heat production is fully radiogenic, with K/U fixed at the terrestrial value and Th/U at the chondritic value, which seems consistent with terrestrial observations. All the abundances are rescaled so as to provide the full 40 TW heat flow. All particle production rates are correspondingly rescaled by a factor of two with respect to the predictions of the BSE model. Concentration of U in the mantle of this model is about 0.03 ppm.

D. Modified Fully Radiogenic (FR II) Model

This model is similar to the previous one, the abundances of U and Th are also rescaled with respect to BSE but it assumes that as an extreme case, the total heat flow of 40 TW are produced in the Earth only by U and Th, completely ignoring K, as considered in Ref. [4]. This is an extreme, geo-antineutrino fluxes much larger than this limit would need serious alteration of source distribution.

III. ANALYSIS METHOD

Here we explain how we calculate the expected number of geo-antineutrino events, for each one of the four models presented in the previous section, at a certain detector position for a given exposition. To try to distinguish models we have used a χ^2 function minimization which is explained at the end of this section.

A. Calculation of the antineutrino fluxes from Th and U decay chains

We would like to calculate the flux of antineutrino produced in the Earth by the decay of a certain isotope that reach a detector for all four geophysical models presented in the previous section. Following Ref. [5], differential flux of antineutrinos produced in the decay chain of radioactive isotope X that will be measured at a detector position $\vec{R}$ on the Earth,

can be expressed by the following integral performed over the Earth volume $V_\oplus$,

$$\frac{d\Phi_{\bar{\nu}_e}(X)}{dE_{\bar{\nu}_e}} = \int_{V_\oplus} d^3r \frac{\rho(\vec{r})}{4\pi|\vec{R}-\vec{r}|^2} \frac{C(X,\vec{r})n_X}{\tau_X m_X} P_{\bar{\nu}_e}(E_{\bar{\nu}_e}, |\vec{r}-\vec{R}|) \times f_X(E_{\bar{\nu}_e}), \tag{1}$$

where $\rho(\vec{r})$ is the matter density, $C(X,\vec{r})$, τ_X and m_X are, respectively, the concentration, life time and atomic mass of element $X = $ U, Th and n_X is the number of antineutrinos emitted per decay chain. $f_X(E_{\bar{\nu}_e})$ is the normalized spectral function for element X [14], $P_{\bar{\nu}_e}(E_{\bar{\nu}_e}, |\vec{r}-\vec{R}|)$ is the $\bar{\nu}_e$ survival probability, which can be averaged out, as a good approximation, and bring out of the integral the term:

$$\langle P_{\bar{\nu}_e} \rangle \simeq 1 - \frac{1}{2}\sin^2 2\theta_\odot \simeq 0.58, \tag{2}$$

where $\theta_\odot$ is the mixing angle responsible for the solar neutrino problem, which is fixed to the current best fitted value, $\sin^2 2\theta_\odot = 0.83$, obtained by combining the solar neutrino and KamLAND data [17]. We note that the matter effect is very small and therefore, can be safely neglected in our analysis.

The integration in Eq. (1) can be approximately divided into three distinct contributions, from continental crust (cc), oceanic crust (oc) and mantle (m), assuming that the matter density $\rho(\vec{r})$ and the concentration of X, $C(X,\vec{r})$ are approximately constant within these three regions and ignoring any contribution from the core, as assumed in Ref. [5], as follows,

$$\Phi_{\bar{\nu}_e}(X) \approx \frac{\langle P_{\bar{\nu}_e} \rangle}{4\pi R_\oplus^2} \left[L^{cc}_{\bar{\nu}_e}(X) I_{cc} + L^{oc}_{\bar{\nu}_e}(X) I_{oc} + L^{m}_{\bar{\nu}_e}(X) I_m \right], \tag{3}$$

where $R_\oplus \approx 6370$ km is the radius of the Earth, and we have defined the neutrino luminosity, $L^i_{\bar{\nu}_e}$, and a factor which depend on the crust thickness distribution over the Earth as well as the detector location, I_i $(i = cc, co, m)$, as

$$L^i_{\bar{\nu}_e}(X) = \frac{n_X \bar{C}_i(X) \bar{\rho}_i}{\tau_X m_X}, \tag{4}$$

$$I_i = \frac{R_\ominus^2}{V_i} \int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \, \sin\theta \int_{R_\oplus - h(r,\theta,\phi)}^{R_\oplus} \mathrm{d}r \frac{r^2}{\left|\vec{R}-\vec{r}\right|^2}, \tag{5}$$

where $\bar{C}_i(X)$ and $\bar{\rho}_i$ are respectively the averaged concentration of U or Th and matter density of region i. We can also write the observable luminosities $L^i_{\bar{\nu}_e}(X)$, in units of 10^{24} particles per second, for masses in units of 10^{17} kg, as

$$L^i_{\bar{\nu}_e}(\mathrm{U}) = 7.4\, M_i(\mathrm{U}), \quad L^i_{\bar{\nu}_e}(\mathrm{Th}) = 1.6\, M_i(\mathrm{Th}). \tag{6}$$

In Eq. 5, $h(r,\theta,\phi)$ indicates the thickness of the shell (mantle or crust) at the position (r,θ,ϕ). For the mantle we have simply used $h(r,\theta,\phi) = R_\oplus/2$, giving $I_{\rm m} = 1.6$. For the crust calculation (typical thickness being $\sim$ 35 km for continental crust and $\sim$ 7 km for oceanic one), we have used the Earth Crust $2^\circ \times 2^\circ$ Thickness map [18], which was obtained based on seismology, to compute the $I_{\rm cc,oc}$ at a given detector positions. Earth's crust is divided into 16200 cells of $2^\circ \times 2^\circ$ where within each cell, the crust thickness is assumed to be constant. See Fig. 1 for schematic illustration of the cell. In Fig. 2 we show some iso-contours of Earth crust thickness based on this crustal map model [18] which we will use in this work.

We observe that in our assumption the ratio of the geo-antineutrino fluxes from U and Th does not depend on details of the integration in Eq. (1) but is given by the following simple formula for any model we consider,

$$\frac{\Phi_{\bar{\nu}_e}({\rm U})}{\Phi_{\bar{\nu}_e}({\rm Th})} = \frac{M({\rm U})\, n_{\rm U}\, \tau_{\rm U}^{-1}}{M({\rm Th})\, n_{\rm Th}\, \tau_{\rm Th}^{-1}} \simeq 1.2, \tag{7}$$

where the ratio of total amount of Th and U, $M({\rm Th})/M({\rm U})$, is assumed to be 3.8 in any of the input model we consider.

We have thus the basic equations for determining radiogenic heat production and neutrino flows from models of the Earth composition. In order to have some feeling about the local variation of geo-antineutrino fluxes due to the variable crustal thickness, in Fig. 3, we present the normalized cumulative geo-antineutrino flux coming from the continental as well as oceanic crust (without contributions from the Mantle) at Kamioka, Gran Sasso, Homestake and Sudbury, as a function of the distance (L) from the source to the detector, computed using the information from the $2^\circ \times 2^\circ$ Earth Crust thickness map [18]. Since the typical size of the crustal cell at these detector sites is of the order of 100 km, we can only reliably compute for distances equal or larger than this. In Fig. 3 we have extrapolated each curve down to 10 km, as a first approximation. For the sake of comparison, we have also plotted the hypothetical case where the entire Earth crust has a uniform thickness of 30 km. Neutrino oscillations were not taken into account in the calculation of the upper five curves but were included in the lower five. These latter curves have been normalized with respect to the no oscillation case. From this plot, as far as geo-antineutrino flux coming from Earth crust is concerned, we can see that about 30-40 % of the total flux comes from the distance within

100 km and about 50-60 % comes from the distance within 500 km from the detector. This implies that it is very important to know rather well, with better than $2^\circ \times 2^\circ$ resolution, the variation of the crustal thickness near the detector as well as the local variation of the concentration of radioactive elements.

B. Number of geo-antineutrino events

The number of geo-antineutrino induced events from the decay chain of element X in the i-th energy bin, $N_i(X)$, is:

$$N_i(X) = N_p\, t \int_i dE_{\bar{\nu}_e}\, \epsilon(E_{\bar{\nu}_e})\, \sigma(E_{\bar{\nu}_e})\, \frac{d\Phi_{\bar{\nu}_e}(X)}{dE_{\bar{\nu}_e}}, \tag{8}$$

where N_p is the number of free protons in the fiducial volume of the detector, t is the exposure time, ϵ is the detection efficiency, which is assumed to be 100 % for simplicity. This integral, which is easily computed using the cross section given in Ref. [13], is understood to be performed in a certain energy bin.

We divide the number of events in the positron prompt energy range 0.9-2.6 MeV into 4 bins with an interval of 0.42 MeV following Ref. [8]. Note that the prompt energy $E_{\rm prompt}$ is related to neutrino energy as $E_{\rm prompt} = E_{\bar{\nu}_e} - (m_n - m_p) + 2m_e = E_{\bar{\nu}_e} - 0.78$ MeV where m_n, m_p and m_e are respectively, mass of neutron, proton and electron. The number of events in $i-$th bin is defined as the sum of events coming from U and Th, $N_{\rm geo}(\bar{E}_i) \equiv N_i({\rm U}) + N_i({\rm Th})$. We note that the 1st two lower energy bins contains events coming from both U and Th induced geo-antineutrinos whereas the last two higher energy bins contain only events coming from Th.

C. χ^2 minimization

We define the χ^2 function for our geo-antineutrino analysis as follows,

$$\chi^2_{\rm geo} = \sum_{i=1}^{17} \frac{\left[N^{\rm obs}(\bar{E}_i) - N^{\rm theo}_{\rm geo}(\bar{E}_i) - N^{\rm theo}_{\rm reac}(\bar{E}_i)\right]^2}{N^{\rm obs}(\bar{E}_i) + \left(0.06\, N^{\rm obs}_{\rm reac}(\bar{E}_i)\right)^2}, \tag{9}$$

where $N^{\rm obs}(\bar{E}_i)$, $N^{\rm theo}_{\rm geo}(\bar{E}_i)$ and $N^{\rm theo}_{\rm reac}(\bar{E}_i)$ are respectively, the number of (simulated) observable events (geo-antineutrinos+reactor), the number of theoretically expected events coming

from geo-antineutrinos and from nuclear reactors in the neighborhood of the detector. As mentioned before, geo-antineutrinos will only contribute to the first four bins. We have taken into account in our calculation the total statistical error as well as a 6% systematic error only for reactor neutrino events. Since currently no detector has enough data in the energy region interesting for geo-antineutrino observations, we simulate $N^{\rm obs}(\bar{E}_i)$ according to the Earth composition models, taking into account the reactor background for a given exposure and site. In our simulations we have fixed the neutrino oscillation parameters to the best fitted values of Ref. [17].

Here, for simplicity, we ignore the systematic error for geo-antineutrinos as it is not so important compared to the statistical one, for the exposure we consider in this work.

The above $\chi^2_{\rm geo}$ will be minimized with respect to: $\Phi_{\bar{\nu}_e}(Th)$, $\Phi_{\bar{\nu}_e}(U)$, the total geo-antineutrino flux coming from Th and U at a given detector site; $\Phi_{\bar{\nu}_e}(U)$ assuming Th/U ratio fixed; $\sin^2 2\theta_\odot$ and $M(U)$ the U mass in the mantle, assuming Th/U ratio fixed. In the first two cases the neutrino mixing parameters are fixed to their best fitted values, in the latter only $\Delta m^2_\odot$ is fixed (see the discussion in the following sections for further details).

In addition, for some of our analyses, we have also added the χ^2 function for solar neutrinos, $\chi^2_{\rm sol}$, which was obtained in Ref. [17].

IV. RESULTS

A. Determination of Geo-antineutrino fluxes

We first discuss the determination of geo-antineutrino fluxes at Kamioka as well as Gran Sasso sites where the former (latter) has larger (significantly smaller) reactor neutrino background. In this subsection, we assume that solar neutrino mixing parameter will be determined with a good precision in the future. See, for instance, Ref. [19] for a discussion on the perspectives of future determination of the solar neutrino mixing parameters.

Since we are taking into account the effect of oscillation, the observable flux suffers a reduction of $\langle P_{\bar{\nu}_e}\rangle = 1 - \frac{1}{2}\sin^2 2\theta_\odot \simeq 0.58$, which implies that the original flux is about 1.7 times larger than shown in our plots.

Strictly speaking, experiments can only measure the total flux of geo-antineutrinos for a

TABLE I: Required exposure in units of kt·yr to identify geo-antineutrinos at the 3 σ level, at Kamioka and Gran Sasso for each input model we consider in this work.

Site	Chondritic	BSE	FR I	FR II
Kamioka	1.7	1.3	0.67	0.46
Gran Sasso	0.89	0.71	0.38	0.26

certain energy range, regardless of their origin (mantle, crust). They cannot directly access the amount of U and/or Th in the crust and mantle separately. Therefore, to be more conservative, we first try to consider the total geo-antineutrino fluxes from U and Th as free parameters to be fitted by the data for a given input model assumption. Since we still do not have enough data in the geo-antineutrino energy range ($E_{\bar{\nu}_e} < 3.4$ MeV), currently KamLAND has only about 0.16 kt·yr exposure [8], we have simulated future data according to each one of the Earth composition models. We have used these simulated data points as an input in our analysis. By performing a χ^2 analysis we have investigated if the experiments can correctly reproduce the input data and distinguish among different models.

First we have estimated the required exposure, in units of kt·yr to identify the presence of geo-antineutrino flux for an assumed model input, leaving the two components of the geo-antineutrino flux, coming from U and Th, completely free. The results are shown in Table I. The numbers in the table are the detector exposure, at each site, required to rule out or accept each model. The actual fiducial volume of KamLAND (Borexino) is about 0.4 (0.1) kt, which means one has to multiply by a factor 2.5 (5) the number found in Table I in order to translate it to the actual detector exposure time. As naturally expected, the larger the input flux, the easier to identify the model, and therefore we need a smaller exposure to rule it out. If, for instance, a detector such as KamLAND, does not see geo-antineutrinos at the 3 σ level after 0.46 kt·yr exposure, it can rule out model FR II, but at this point it cannot say anything about the other models. On the other hand, if KamLAND measures geo-antineutrinos at this exposure, then FR II has to be interpreted as the preferred model and so forth.

In Fig. 4, we present in the $\Phi_{\bar{\nu}_e}(\mathrm{U}) - \Phi_{\bar{\nu}_e}(\mathrm{Th})$ plane, to which extent we can determine geo-antineutrino fluxes for given input model fluxes and exposure (in units of kt·yr) at the Kamioka site. In all cases we are able to correctly reproduce the input data. Unfortunately it seems to be extremely difficult to distinguish between BSE and Chondritic models, independently of the detector exposure we have considered here. From this plot, we can conclude that for 1 kt·yr of exposure, it is not possible to distinguish among the four models considered. After 3 kt·yr of exposure, one start to have some sensitivity to distinguish models. However, after the maximal exposure considered, 6 kt·yr of data, one can almost always distinguish FR II from any of the other models. It is worthwhile to note that even for the maximal exposure and maximal flux (FR II) considered here, it is not possible to exclude a null Th flux, whereas it is sometimes possible to exclude a null U flux.

In Fig. 5, we present the same plot but for the Gran Sasso site, assuming a significantly less reactor neutrino background, about 5 times smaller than at the Kamioka site [4]. In this case, one can achieve the same sensitivity for the flux determination with less exposure compared to the Kamioka site. Roughly speaking, x kt·yr exposure at Gran Sasso correspond to $(2-3)x$ kt·yr at Kamioka, which we can see by comparing Figs. 4 and 5. The general behavior of the allowed regions are very similar to that for Kamioka site apart from this difference.

Finally, in Fig. 6, we show with which precision the total U flux can be determined by the experiments, further imposing that the ratio between the total U and Th mass in the Earth is fixed to be constant, $M(\mathrm{Th})/M(\mathrm{U}) = 3.8$, in the χ^2 fit. Note that this reasonable assumption, based on meteorite and Earth surface data, is not very important in distinguishing models but allows for a better precision in flux determination. In this case, we have only one free parameter, $\Phi_{\bar{\nu}_e}(U)$, to be fitted. In 6 kt·yr at Kamioka, the total U flux can be determined within less than 10 %, independently of the model. The precision it can be determined at Gran Sasso, after 2 kt·yr exposure, is a bit over 10 %.

B. Dependence on the solar mixing angle $\theta_\odot$

So far, we have fixed the solar mixing angle $\theta_\odot$ to its current best fitted value. How our ignorance about the actual value of the solar mixing angle can aggravate our results? To

investigate this we perform a fit leaving $\sin^2 2\theta_\odot$ as a free parameter. For this purpose we will combine present solar neutrino data with future simulated reactor and geo-antineutrino data.

As a first step to see how the observation of geo-antineutrinos can affect the determination of the mixing angle, we have analyzed the present KamLAND reactor data (17 bins) allowing for geo-antineutrino contributions in the first 4 bins, as performed by the authors of Ref. [6]. In Fig. 7, we show the result we have obtained. In agreement with the result in Ref. [6], the allowed region becomes somewhat smaller when we include events which can be interpreted as geo-antineutrinos. Some events observed in the energy range $E_{\rm prompt} < 2.6$ MeV are can be attributed to geo-antineutrinos, but the claim that geo-antineutrinos have been observed can not be made at this point due to small statistics (see discussion in previous section).

We further proceed, combining the KamLAND data with the current solar neutrino one. The final result is shown in the right panel of Fig. 8, where we have also presented the result without the geo-antineutrino constraint in the left panel taken from Ref. [17]. The allowed region becomes somewhat smaller but essentially has not changed. This is not a surprise as solar neutrino data are dominating in the determination of the mixing angle at this point.

Next, we combine the simulated future reactor and geo-antineutrino data with the present solar neutrino data. In Figs. 9 and 10 we plot the allowed region for $\Phi_{\bar{\nu}_e}(\mathrm{U})$ and $\sin^2 2\theta_\odot$, assuming the ratio between the total U and Th mass in the Earth to be $M(\mathrm{Th})/M(\mathrm{U}) = 3.8$, for the Kamioka and Gran Sasso sites. The reduction of the allowed range of $\sin^2 2\theta_\odot$ from 1 to 6 kt·yr exposure is essential due to reactor neutrinos. We observe that our ignorance on the exact value of $\theta_\odot$ does not influence very much the determination of $\Phi_{\bar{\nu}_e}(\mathrm{U})$, so our conclusions in the previous subsection do not essentially change.

V. DISCUSSION AND CONCLUSION

The amount of radioactive elements in the Earth is not well known. The total quantity of U and Th in the Earth, however, can be directly measured by neutrino detectors. Presently KamLAND data imply that the Earth radiogenic heat output can be anything between 0 and 110 TW. We have studied how this can be improved by future data.

We have investigated to which extent U and Th geo-antineutrino fluxes can be determined

by neutrino detectors in a decade of exposure. We have considered KamLAND at Kamioka and Borexino at Gran Sasso as our reference detectors and sites. We have found, as we showed in Table I, that within a few years with a relatively small amount of exposure, it is possible to establish the presence of geo-antineutrinos unless their flux is significantly smaller than expected. However, to discriminate among different Earth composition models considerably longer exposure is required. We found that in 6 kt·yr at Kamioka, the total U flux can be determined within less than 10 %, independently of the model we considered. The precision it can be determined at Gran Sasso, after 2 kt·yr exposure, is a bit over 10 %. We note that at Gran Sasso the same sensitivity to geo-antineutrino flux determination can be achieved with substantially smaller exposure due to much lower reactor antineutrino background.

We observe that our ignorance on the exact value of $\theta_{\odot}$ does not influence very much the determination of the geo-antineutrino flux. However, it is very important to know the local variation of the Earth crustal thickness as well as concentration of U and Th in the region close to the detector with better than $2^{\circ} \times 2^{\circ}$ resolution, to be able to accurately translate the measured flux into amounts of U and Th.

The determination of the radiogenic component of the Earth heat generation is of great geophysical interest. Experiments such as KamLAND and Borexino can open a new window to survey the internal structure and dynamics of our planet.

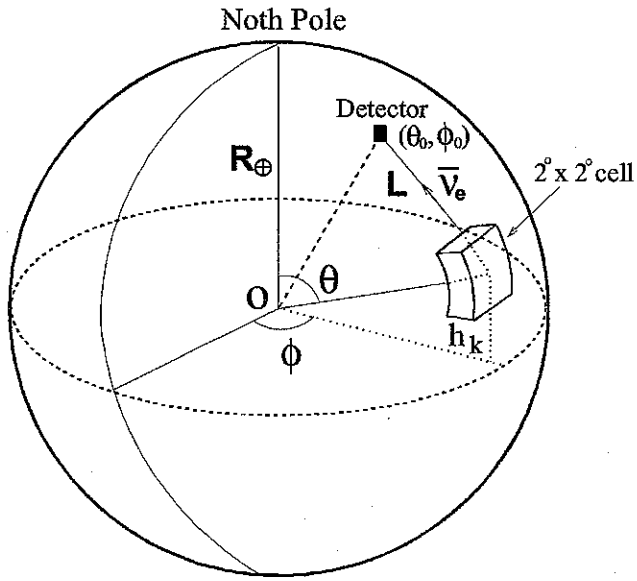

FIG. 1: Schematic illustration of the k-th cell of the Earth crust in which its thickness is assumed to be constant.

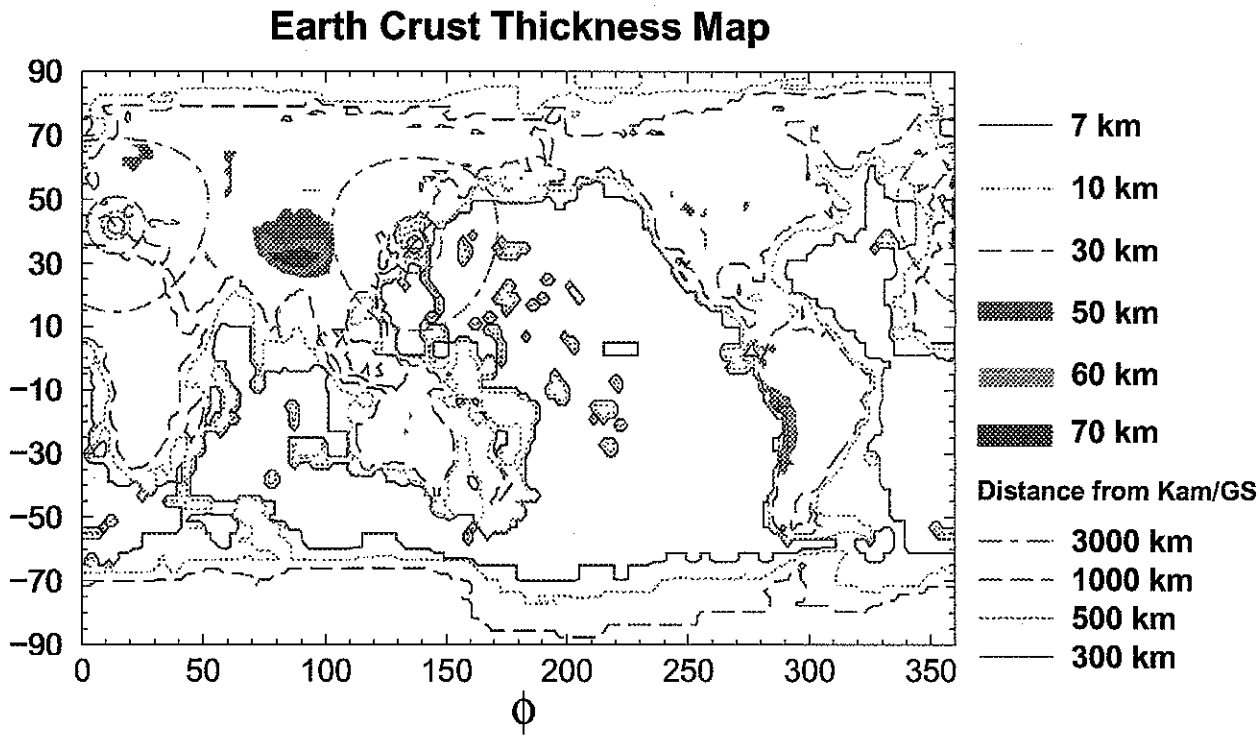

FIG. 2: Iso-contours of the Earth crust thickness based on the global 2° × 2° crustal map [18] we adopted in this work.

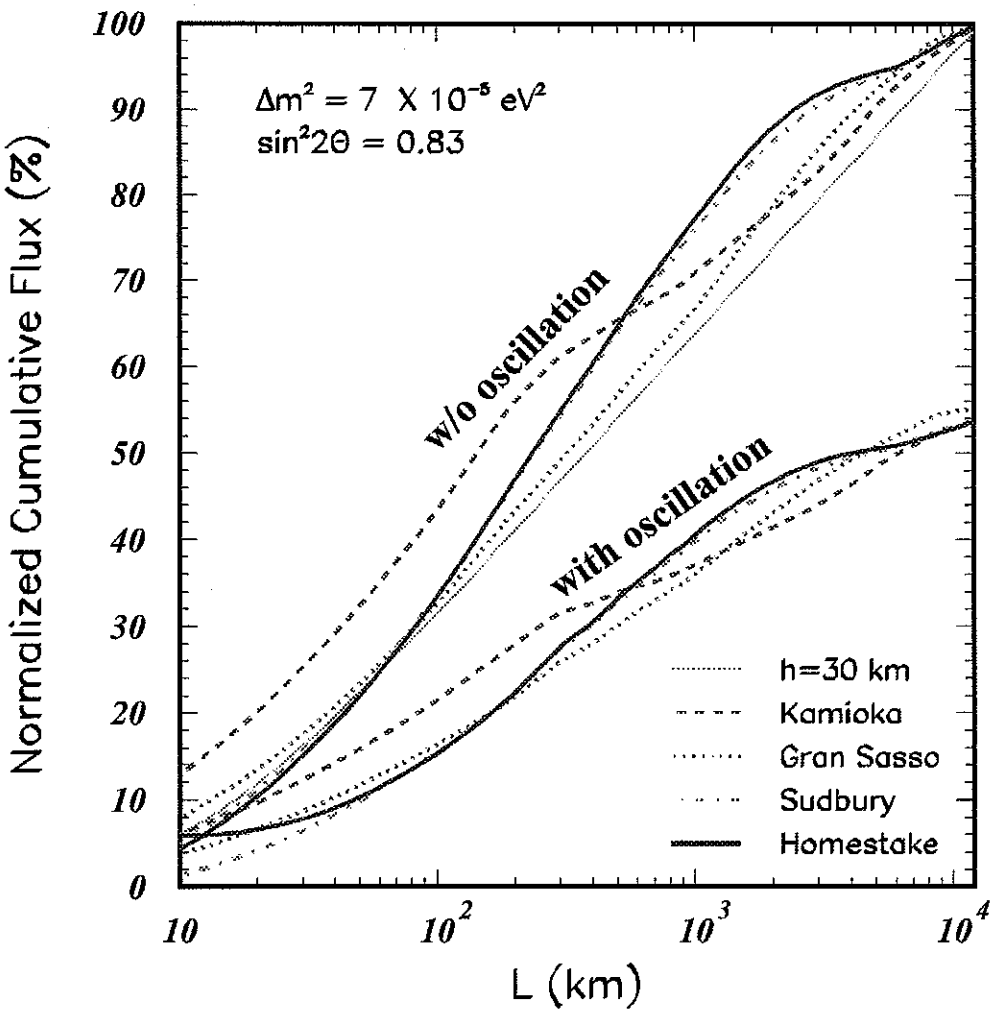

FIG. 3: Normalized cumulative geo-antineutrino flux, with (lower five curves) and without (upper five curves) neutrino oscillation, coming from the continental as well as oceanic crust (without contributions from the Mantle) at various positions on the surface of the Earth as a function of the distance (L) from the source to the detector. These curves were computed using the information from the $2^\circ \times 2^\circ$ Earth Crust thickness map [18]. For the sake of comparison, we have also plotted the hypothetical case where the entire Earth crust has a uniform thickness of 30 km.

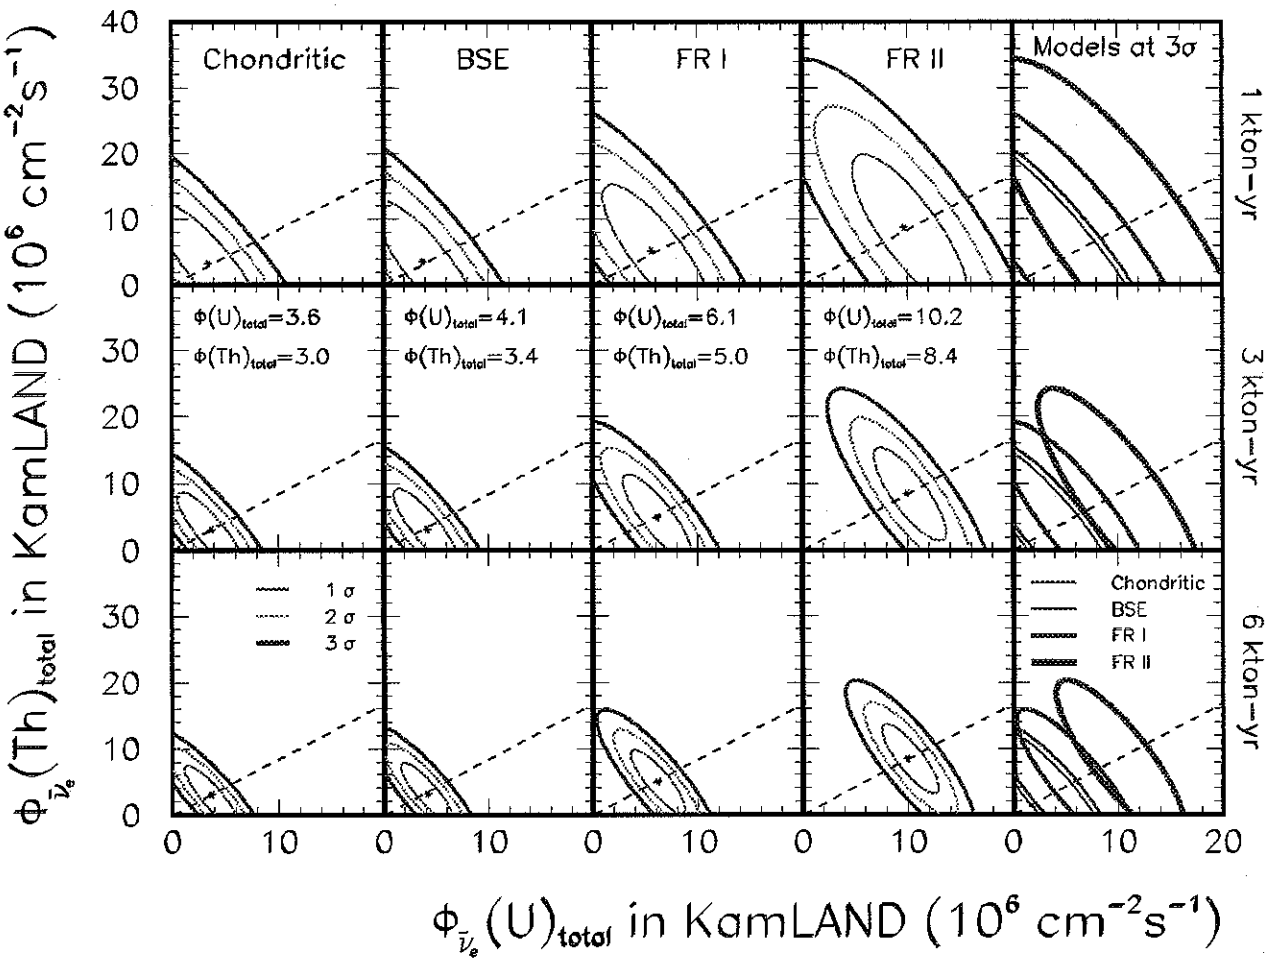

FIG. 4: Region allowed at 1, 2 and 3 σ in the $\Phi_{\bar{\nu}_e}(\mathrm{U}) - \Phi_{\bar{\nu}_e}(\mathrm{Th})$ plane, for 4 different models (in first 4 columns) for 1, 3 and 6 kt· yr of exposures (in different rows). In the 5th column, we have superimposed 3 σ allowed regions of 4 different models. In the second row, for each model, the input values for the geo-antineutrino fluxes, computed according to Eq. 1 using the information from the Earth Crust $2^\circ \times 2^\circ$ Thickness map [18], are indicated. Both of $\Phi_{\bar{\nu}_e}(\mathrm{U})$ and $\Phi_{\bar{\nu}_e}(\mathrm{Th})$ fluxes are allowed to vary freely.

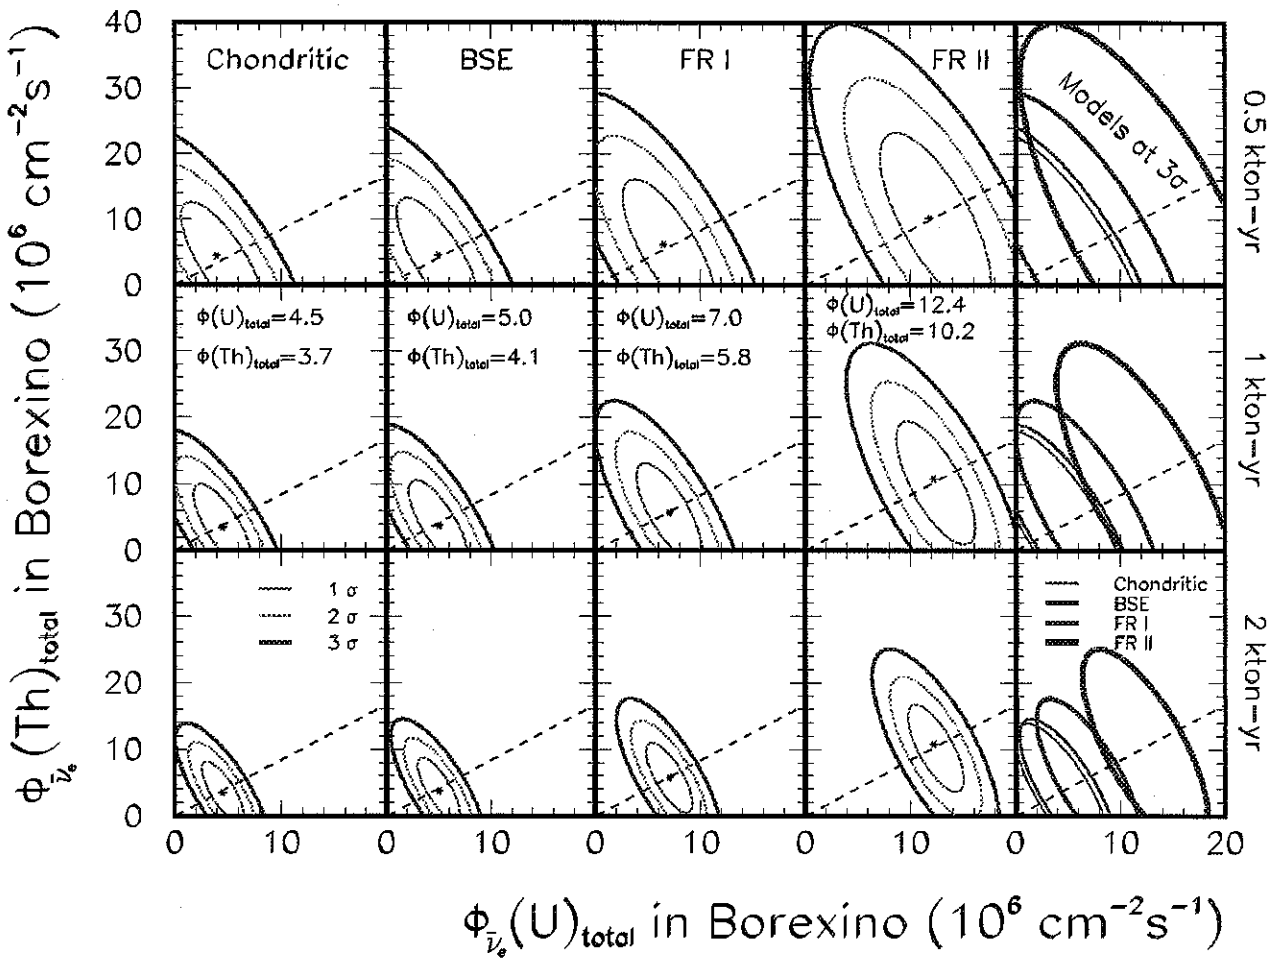

FIG. 5: Same as in Fig. 4 but for the Gran Sasso site.

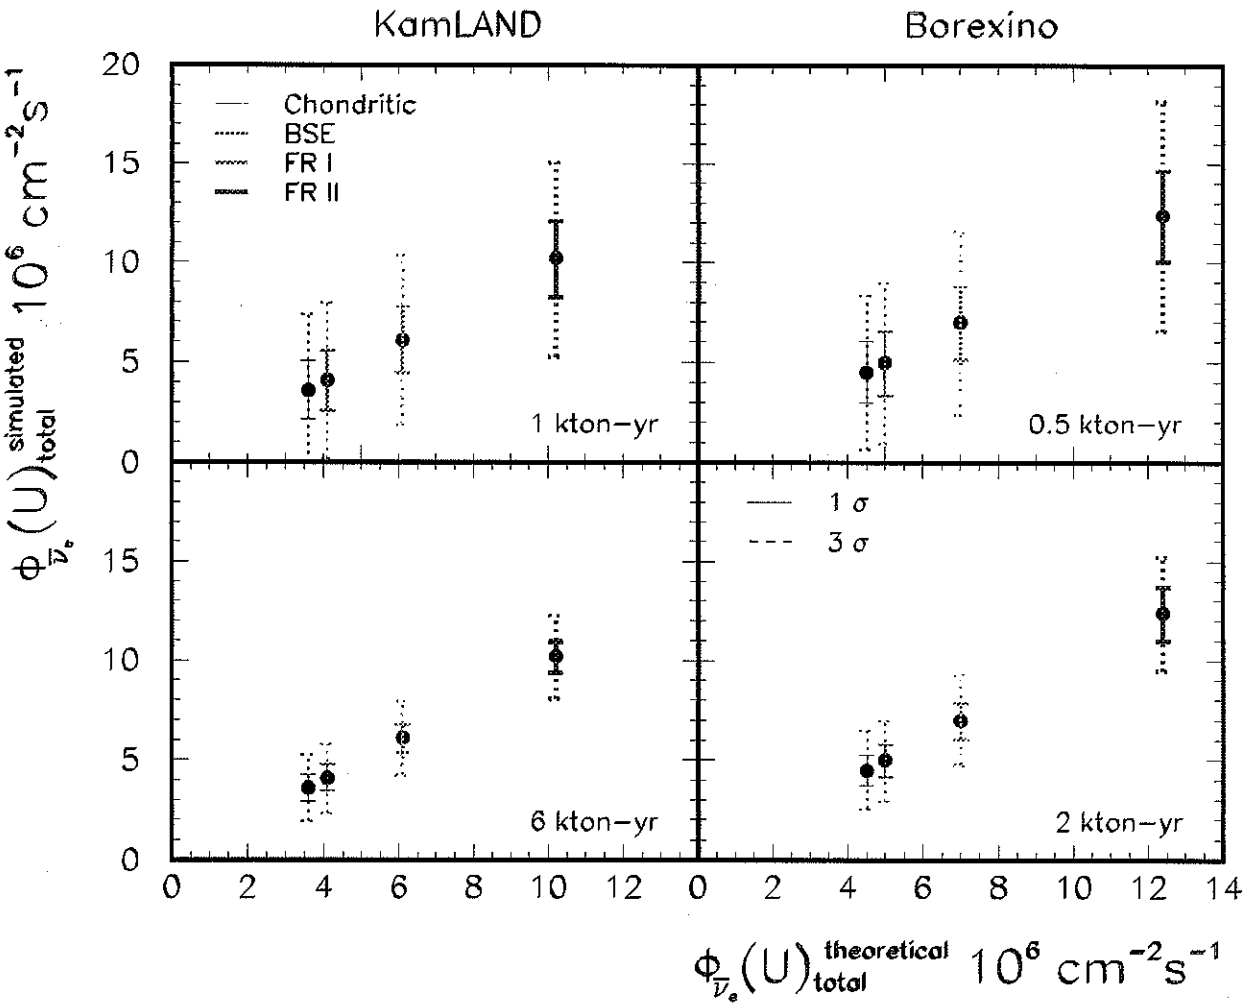

FIG. 6: The allowed ranges of geo-antineutrino flux from U are plotted for given different input flux assuming $M(\mathrm{Th})/M(\mathrm{U}) = 3.8$ for KamLAND for 1 and 6 kt· yr of exposures and for Borexino for 0.5 and 2 kt· yr exposures.

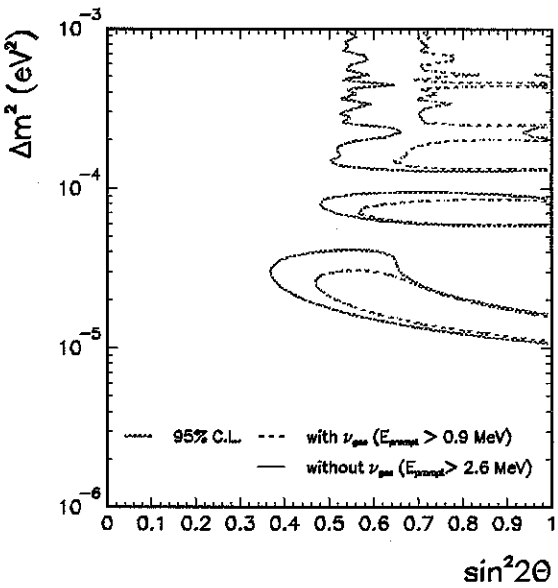

FIG. 7: Regions in $(\sin^2 2\theta_{\odot}, \Delta m^2)$ plane allowed by KamLAND data alone (without solar neutrino data) for different thresholds $E_{\rm prompt} > 0.9$ MeV (including geo-antineutrino candidates) and $E_{\rm prompt} > 2.6$ MeV (without geo-antineutrinos contribution).

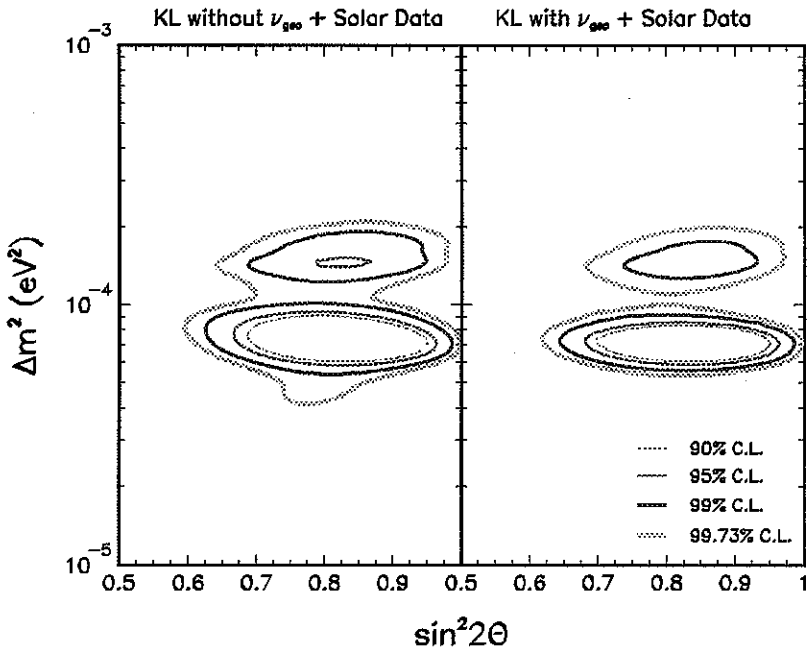

FIG. 8: Region allowed by all the solar neutrino experiments combined with KamLAND data with different thresholds $E_{\rm prompt} > 2.6$ MeV (left panel) and $E_{\rm prompt} > 0.9$ MeV (right panel).

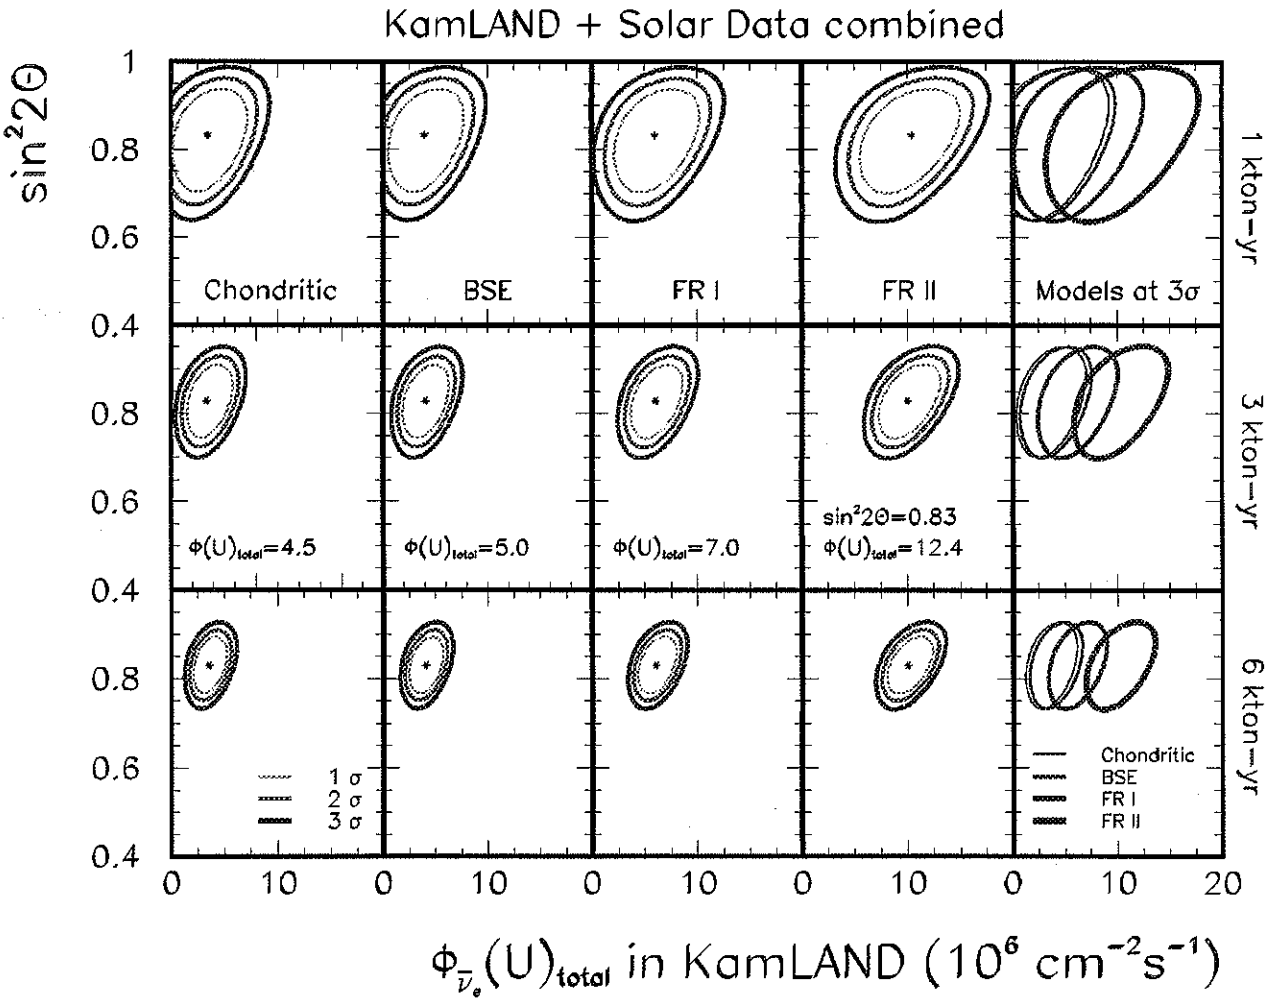

FIG. 9: Region allowed at 1, 2 and 3 σ in the $\Phi_{\bar{\nu}_e}(\mathrm{U}) - \sin^2 2\theta_\odot$ plane, for 4 different models (in first 4 columns) for 1, 3 and 6 kt· yr of exposures (in different rows). In the 5th column, we have superimposed 3 σ allowed regions of 4 different models. Here the flux ratio of $\Phi_{\bar{\nu}_e}(\mathrm{U})$ and $\Phi_{\bar{\nu}_e}(\mathrm{Th})$ is fixed to be constant.

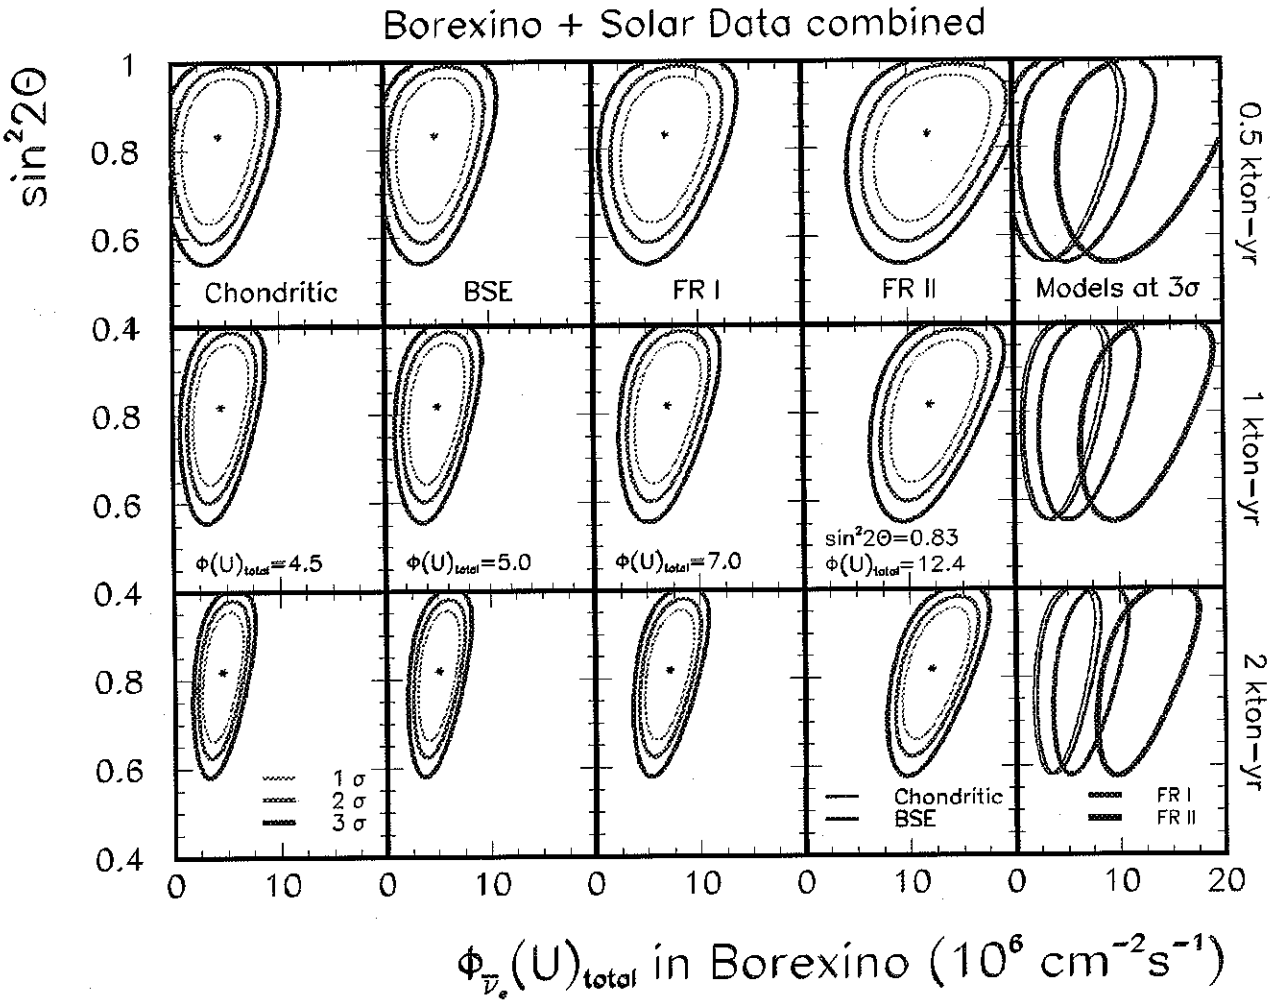

FIG. 10: Same as in Fig. 9 but for the Gran Sasso site.
